

# CS184 Project 4

Matthew Tang, Kaitlyn Lee

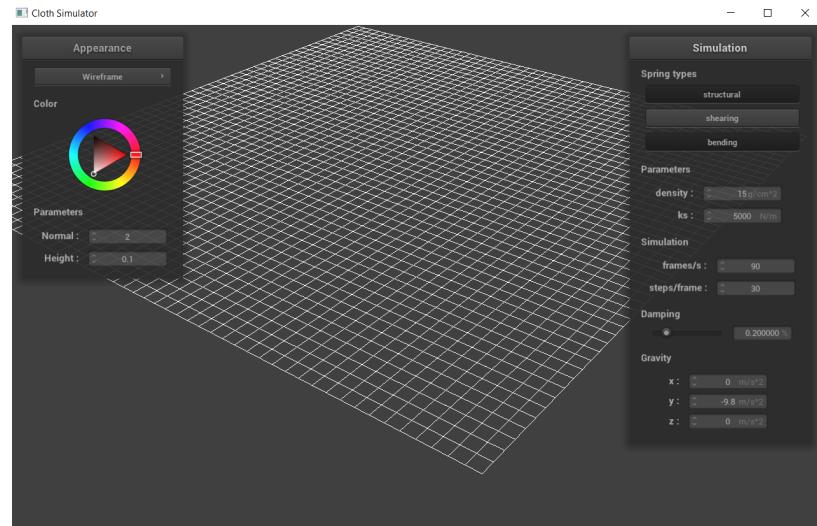

<https://cal-cs184-student.github.io/sp22-project-webpages-kaitlynlee/proj4/index.html>

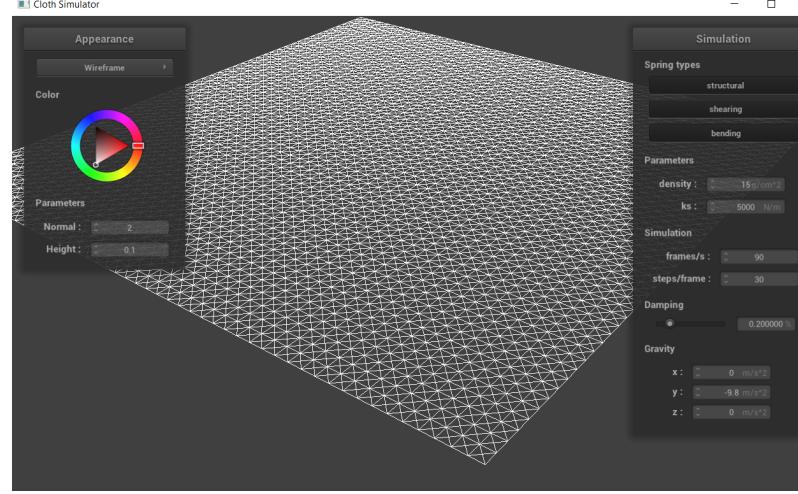

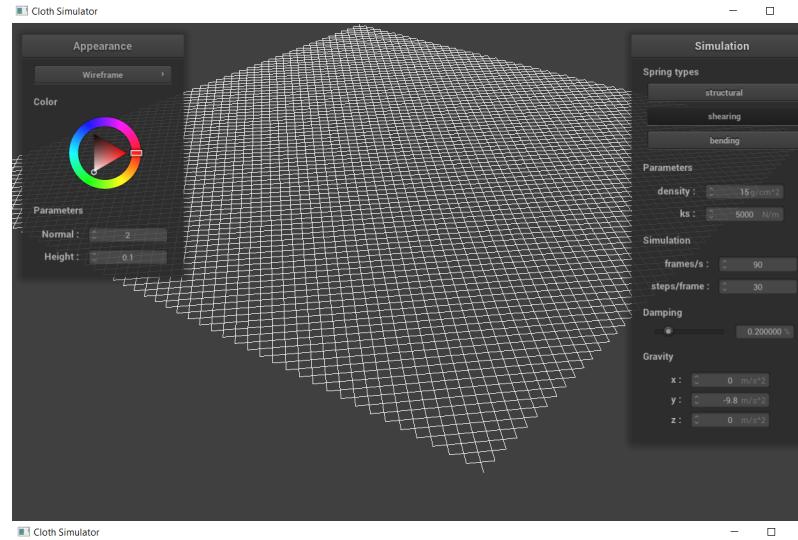

## Part 1

In Part 1, we implemented code to set up the masses and springs. We implemented 3 types of constraints: structural, shearing, and bending. The below image shows the top view of the wireframe with all constraints.

These images show what the wireframe looks like (1) without any shearing constraints, (2) with only shearing constraints, and (3) with all constraints.

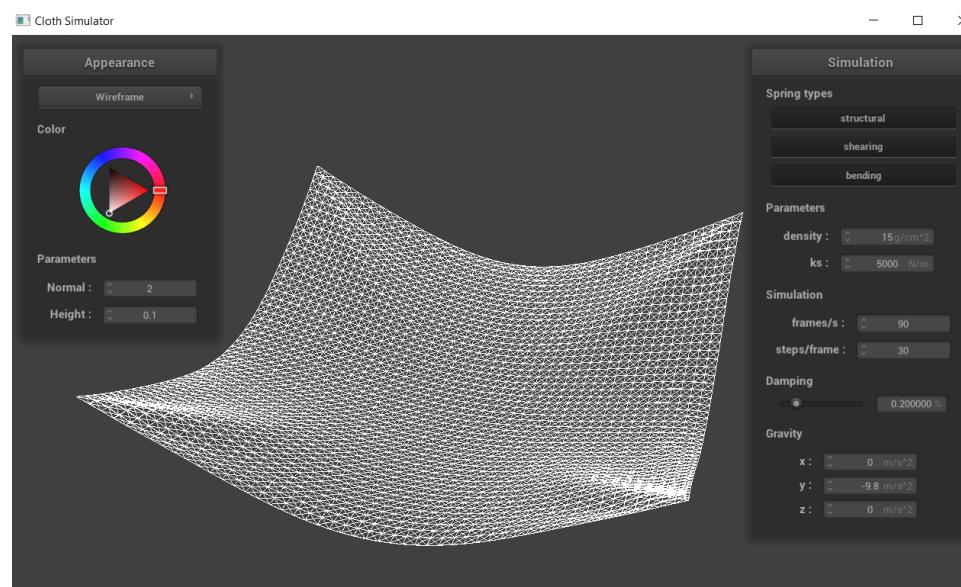

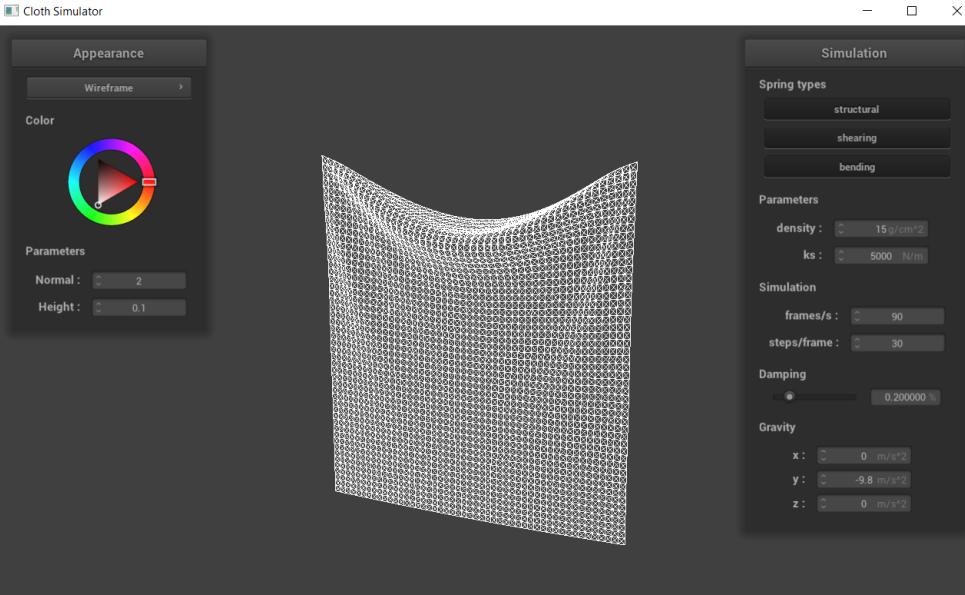

## Part 2

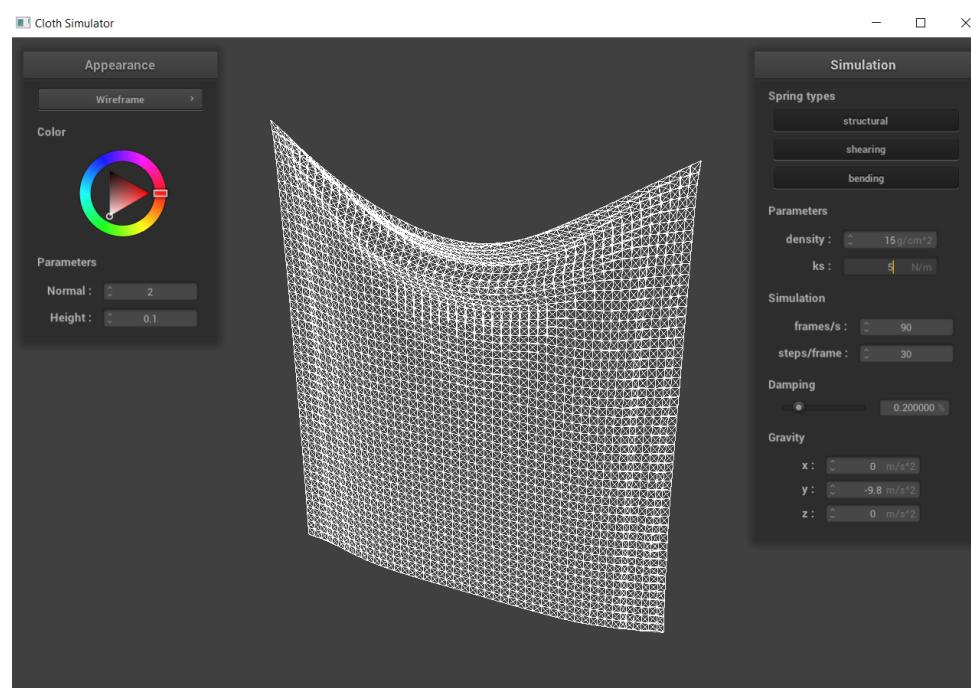

In Part 2, we computed the total force acting on each point mass and used verlet integration to compute new mass positions. We also made sure add a constraint such that the spring's length is at most 10% greater than its rest\_length at the end of any time step.

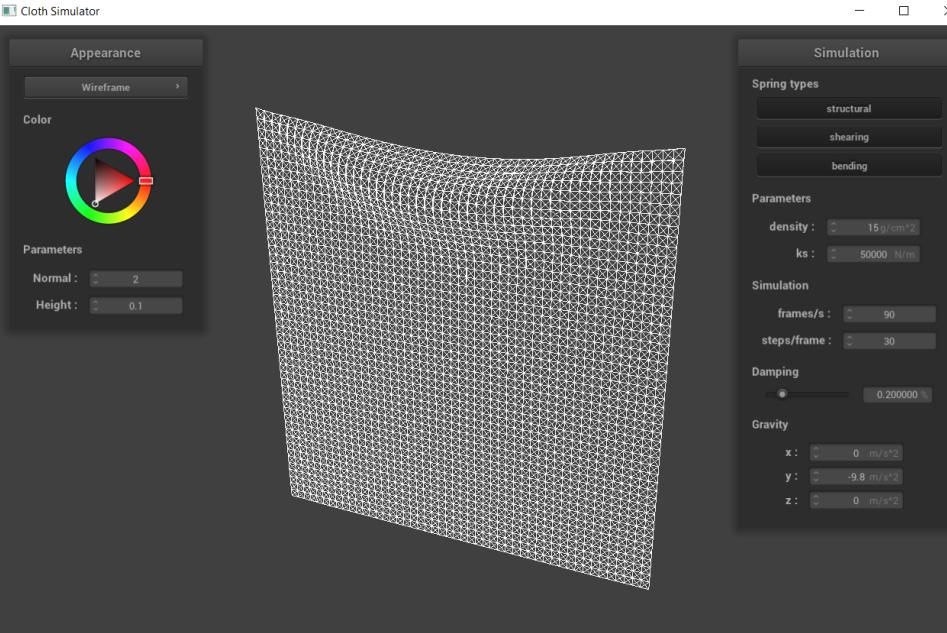

Here is the final resting state of pinned4 and pinned2 respectively.

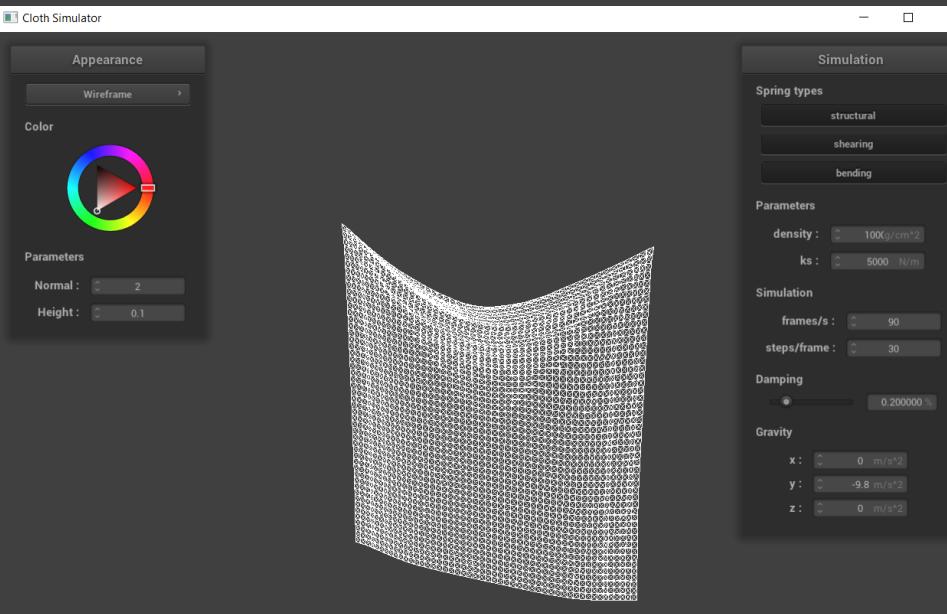

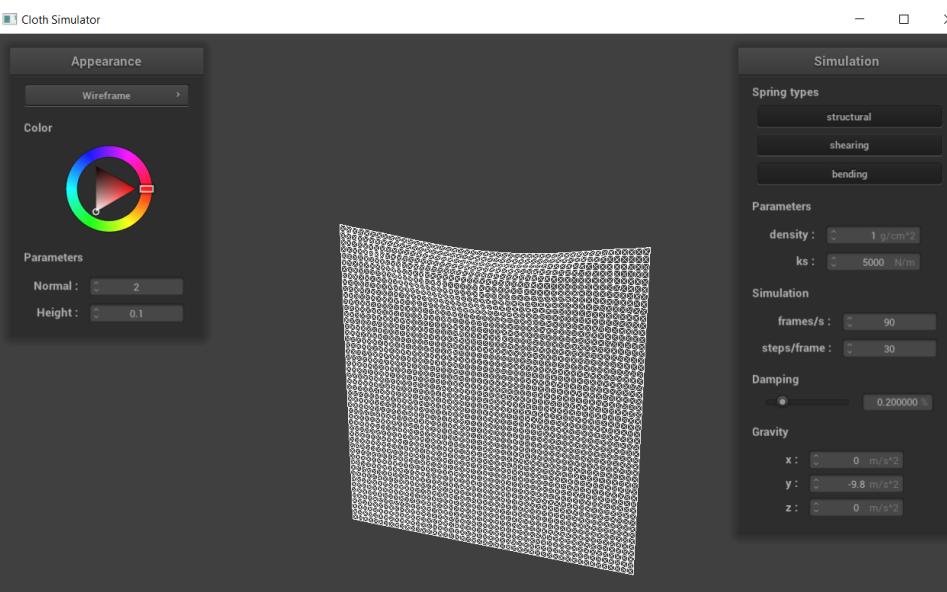

Setting the ks to be very low makes the cloth fall slower and droop more in its final resting state. There are more random jitters in the resting state. Setting the ks to be high makes the cloth fall faster and settle faster. The final resting state is more taut. (Setting the ks to be ridiculously high will produce a degenerate blob, but we assume that ks is not that high.) The left photo shows a low ks and the right photo shows a high ks.

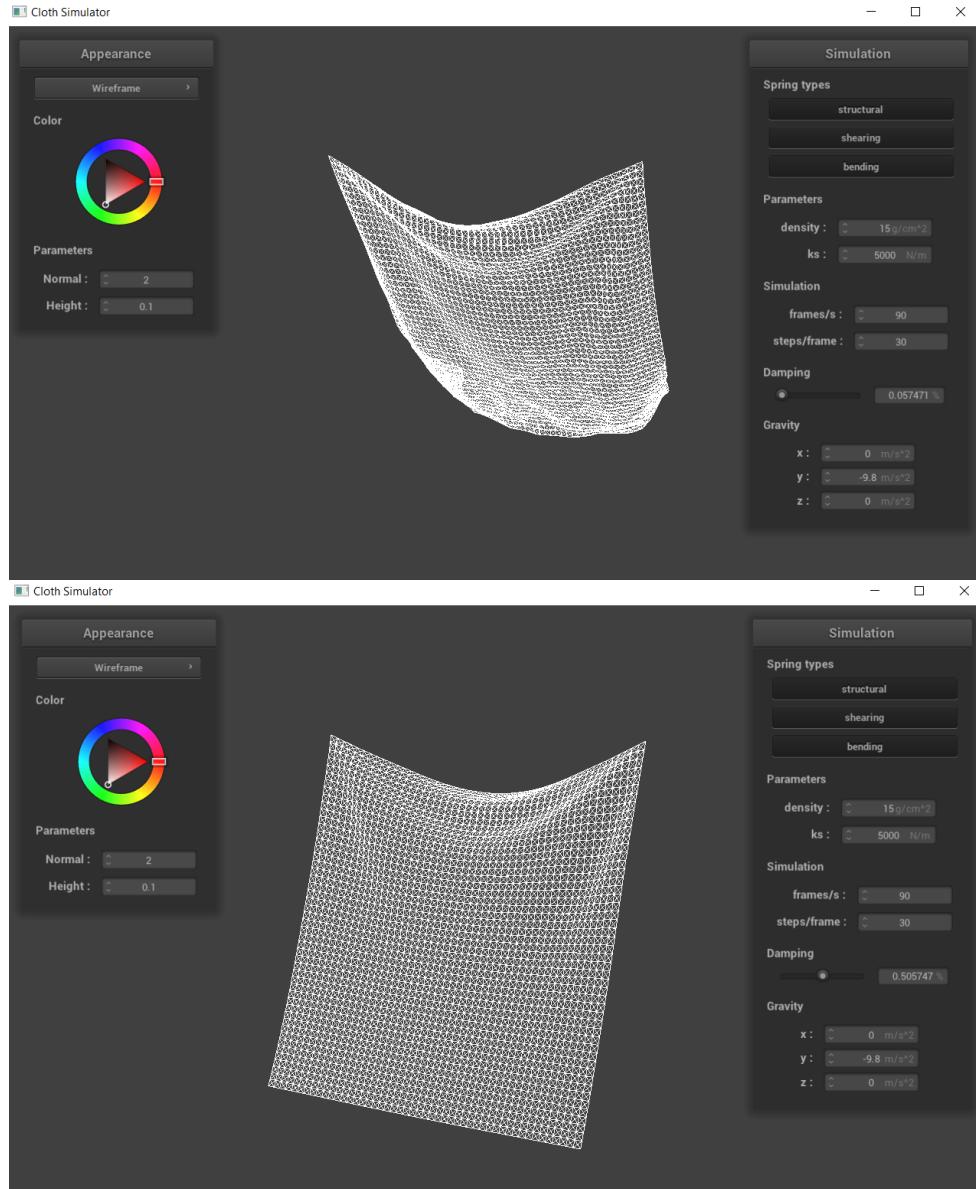

A low density also creates a similar taut resting state. A high density creates a very droopy resting state. The left photo shows a low density and the right photo shows a high density.

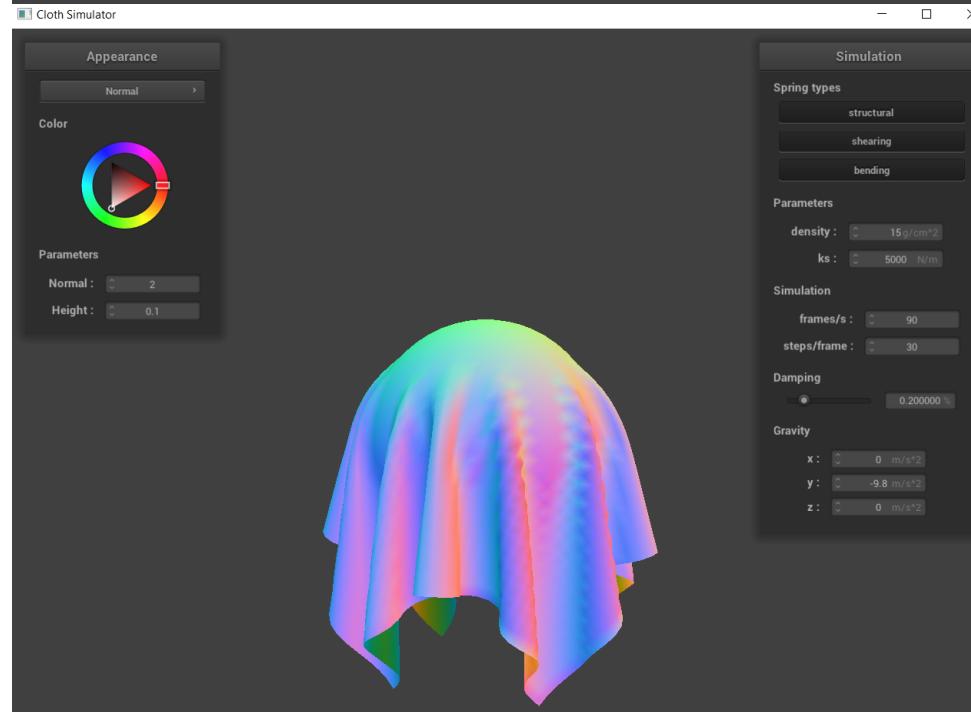

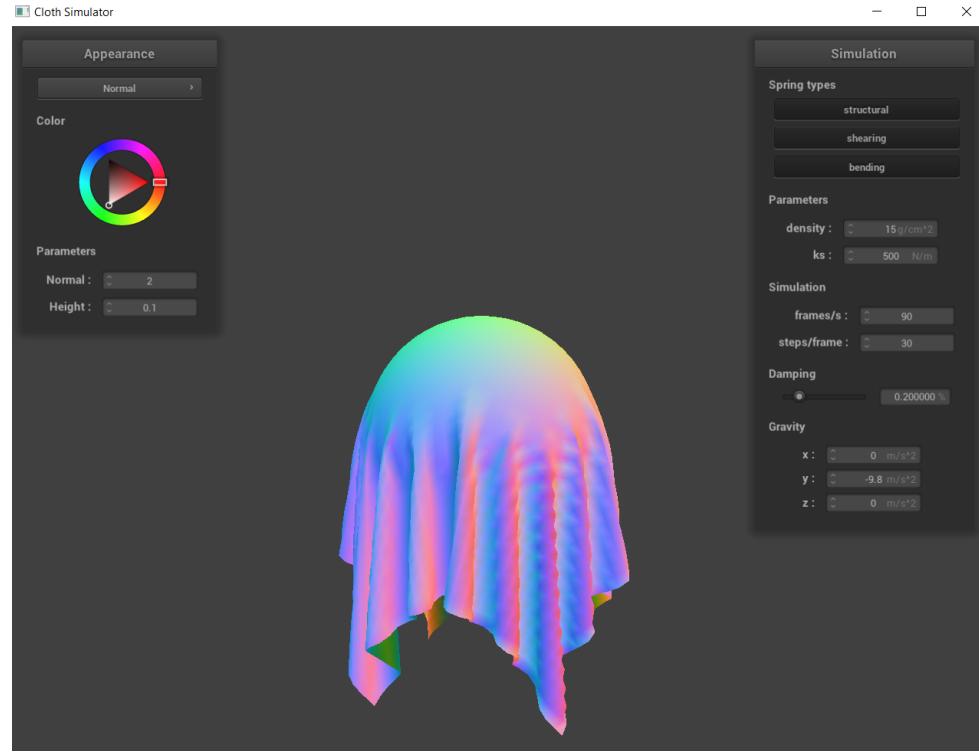

Low damping means it takes longer for the cloth to settle and it will swing back and forth. High damping means the cloth will take a long time to fall down and settle into its resting position as well. The below screenshots (low damping, high damping) were taken before they reached their resting positions.

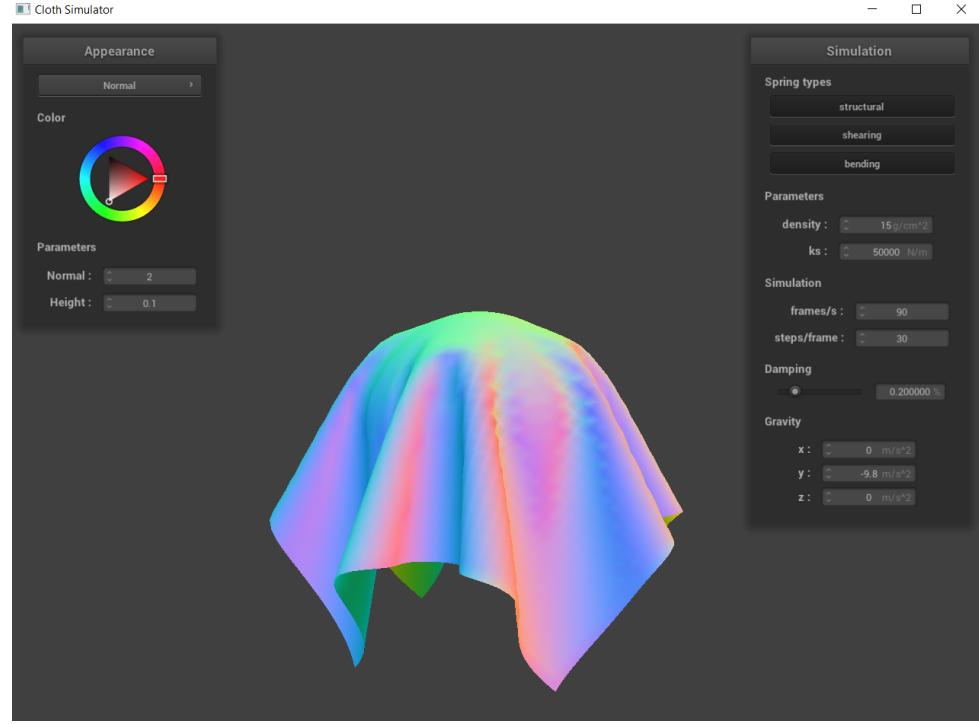

## Part 3

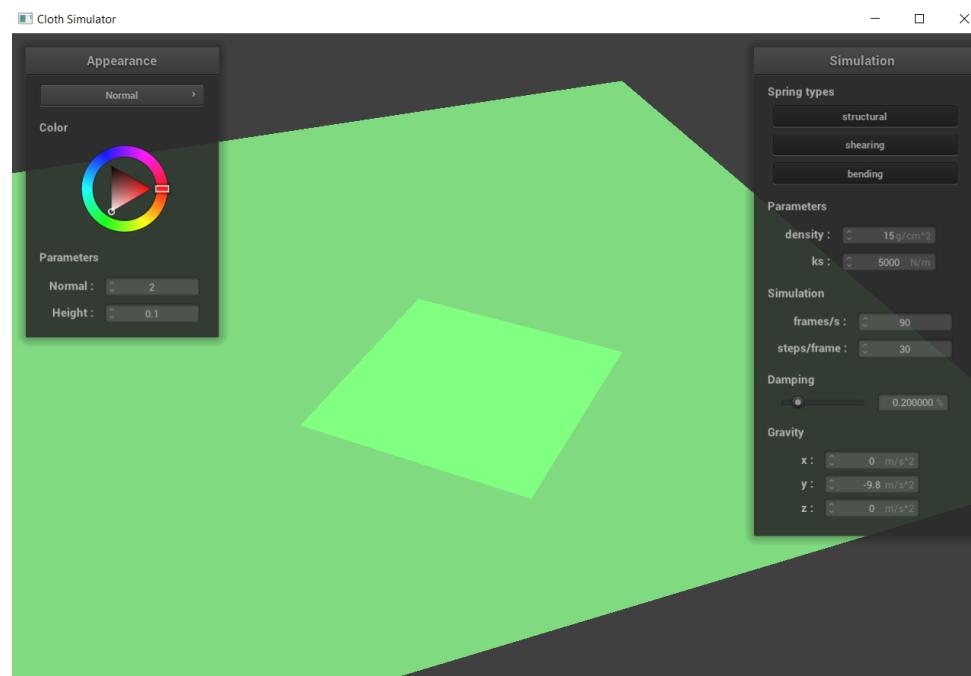

In Part 3, we implemented collisions with planes and spheres.

We can play around with different ks values for the sphere. The smaller the ks value, the more droopy it looks. The cloth conforms more to the surface of the sphere. The higher the ks value, the more taut it looks. The high ks value screenshot shows the cloth being very stiff and not conforming to the shape of the sphere very well. The default ks value is an inbetween of the two extremes.

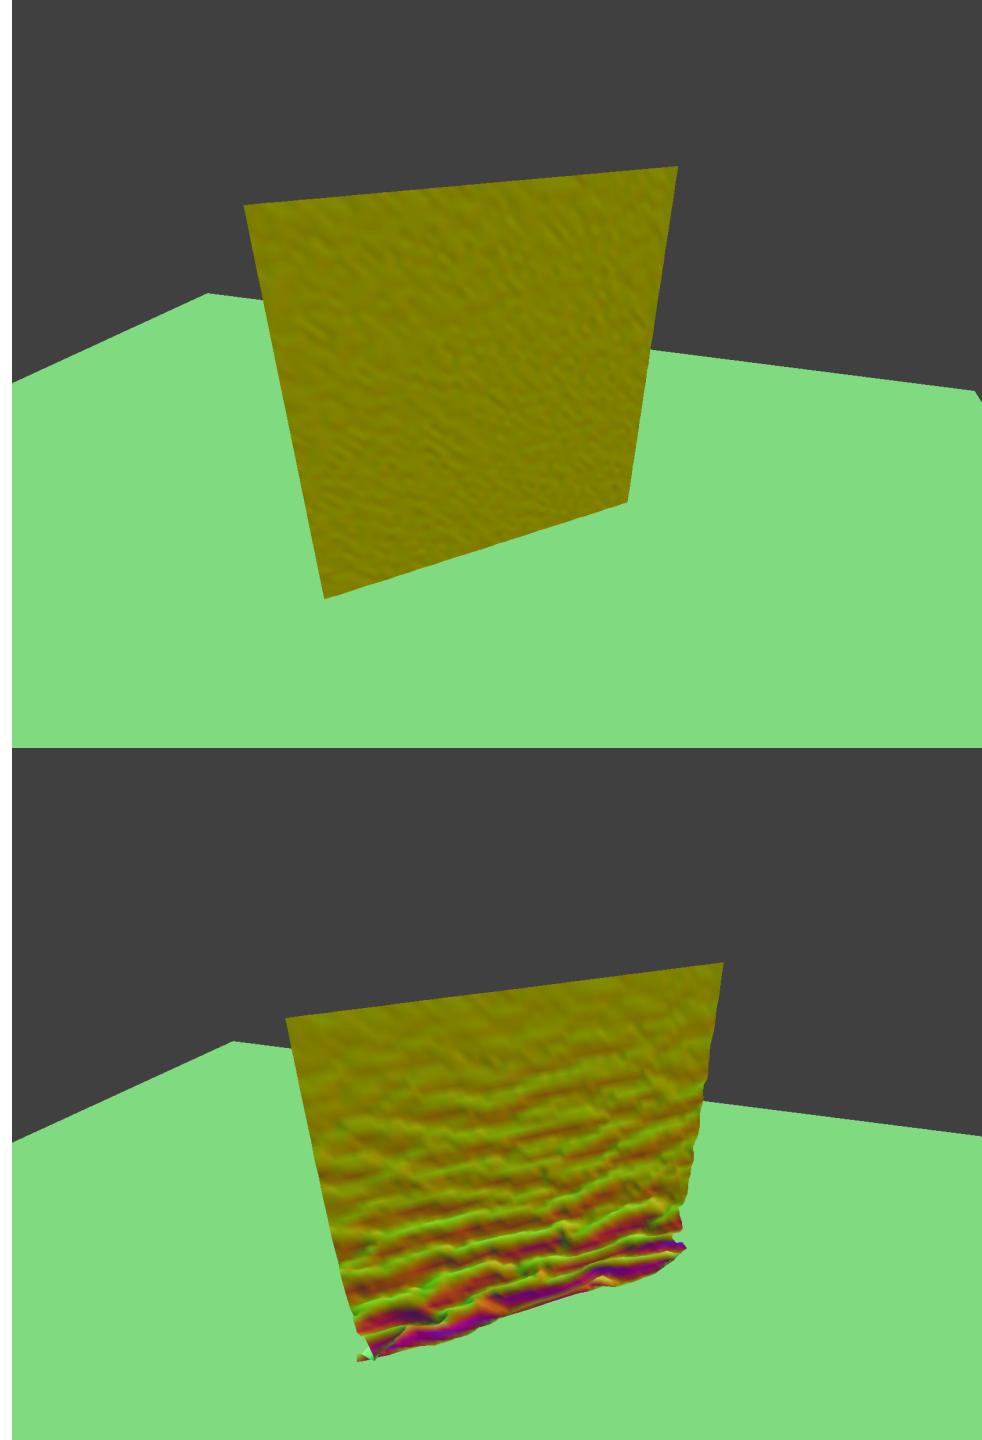

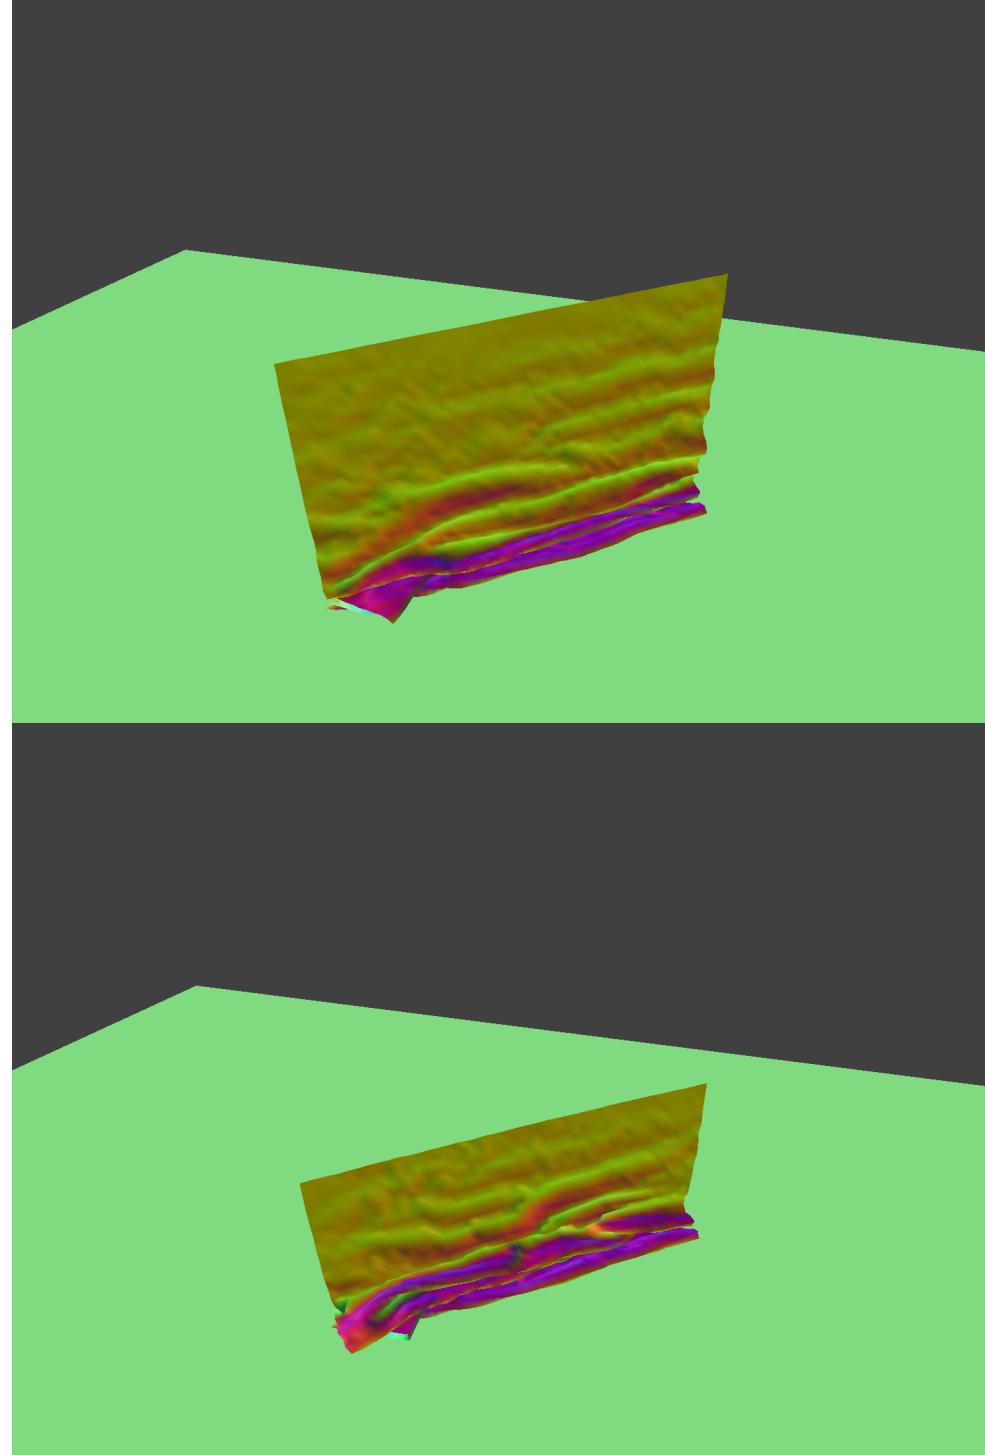

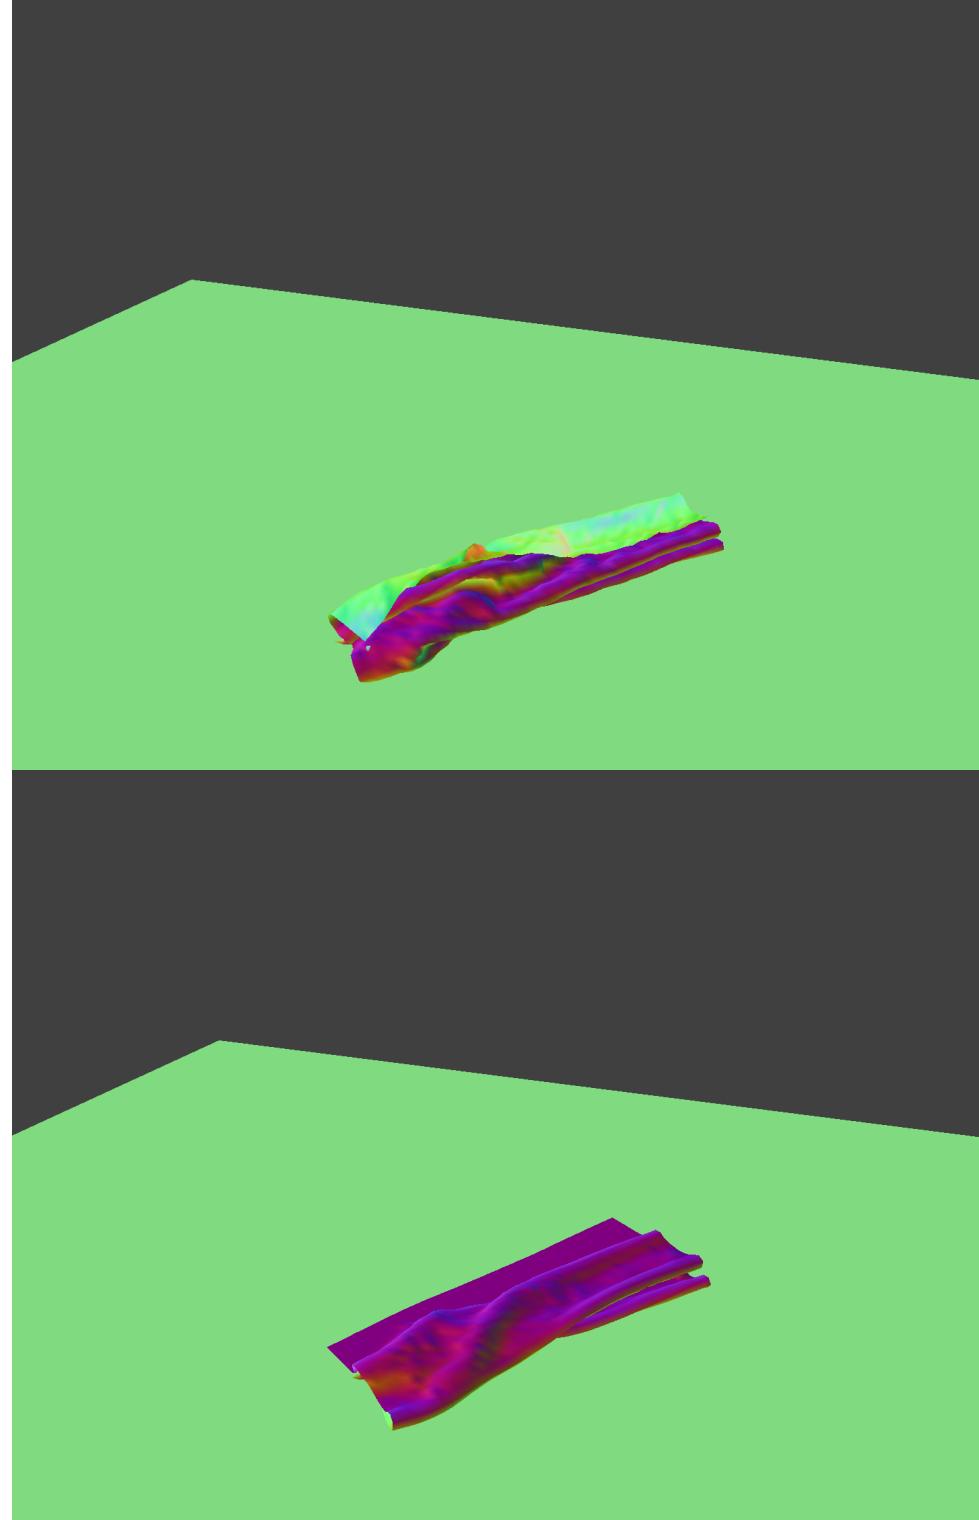

Here is a screenshot of the cloth lying on the plane at rest.

## Part 4

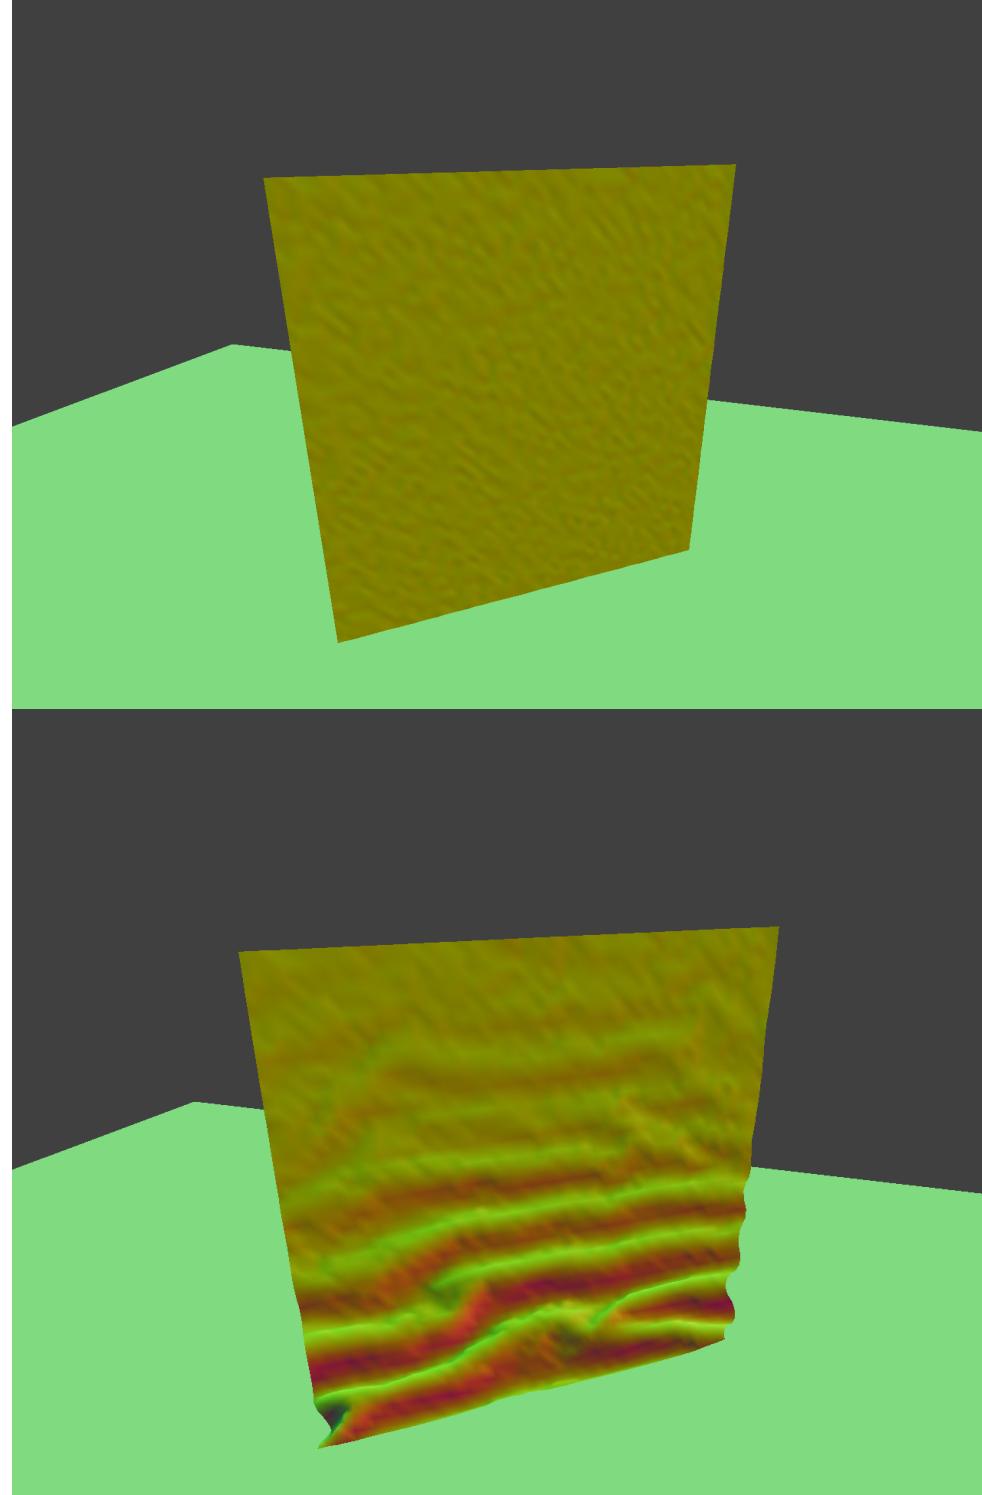

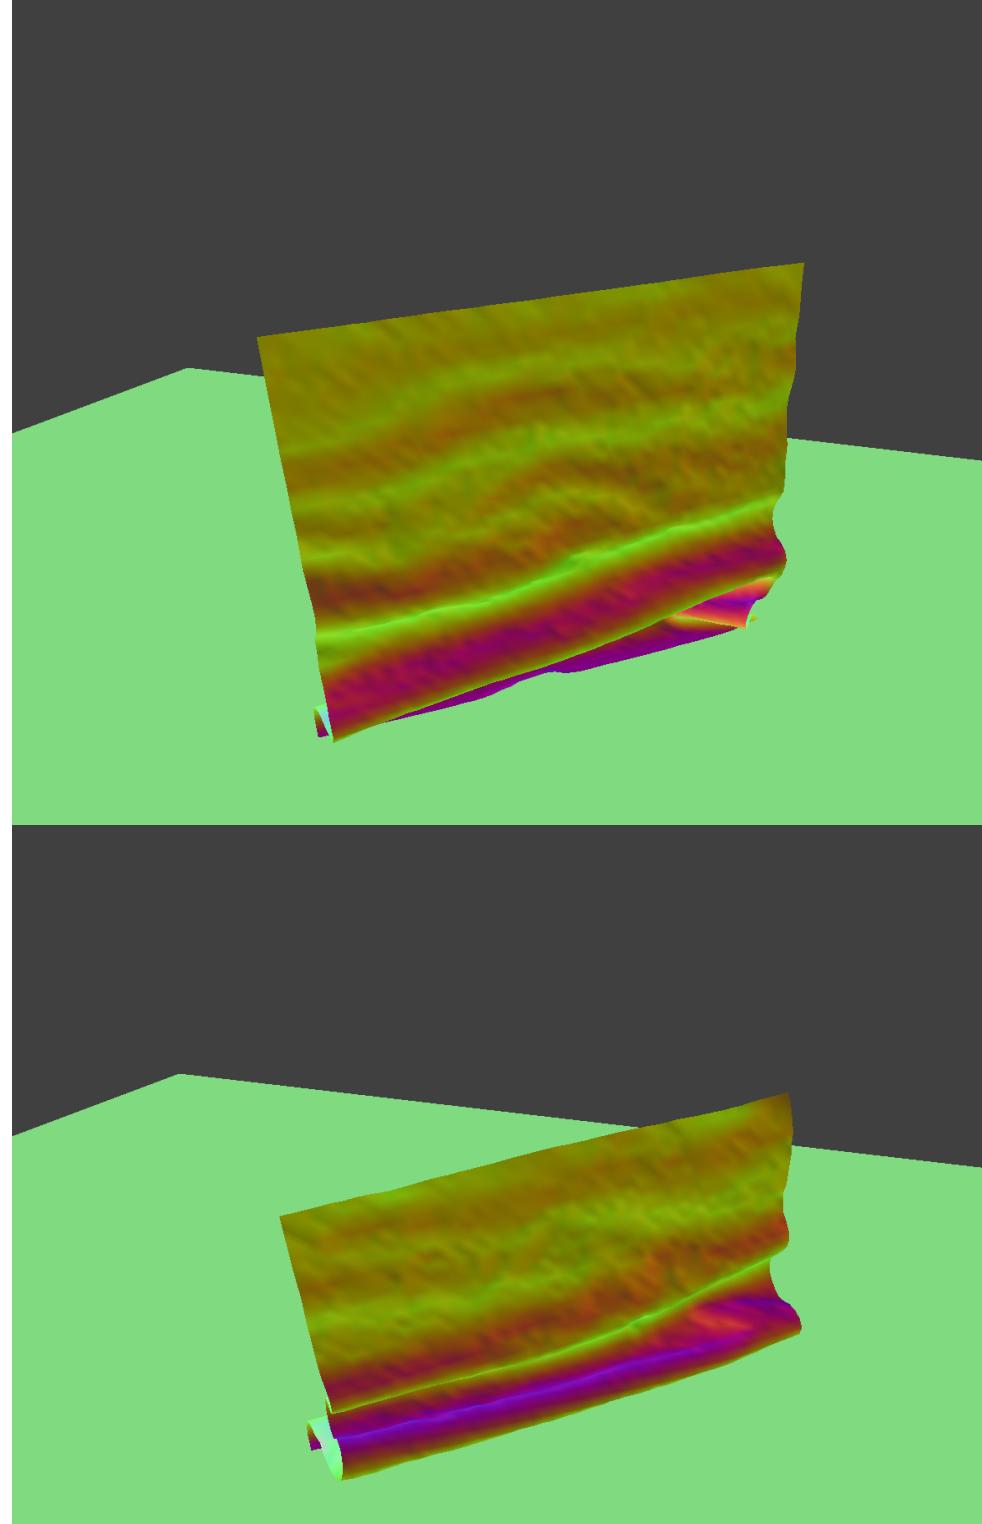

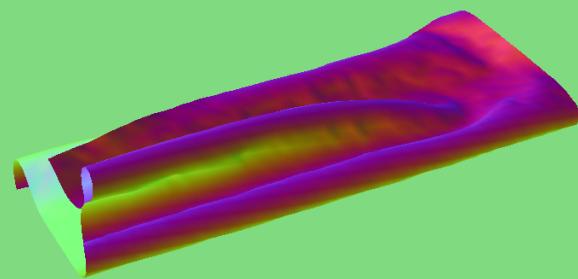

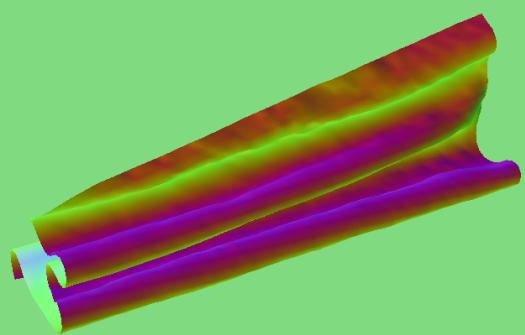

#### Varying d and ks values

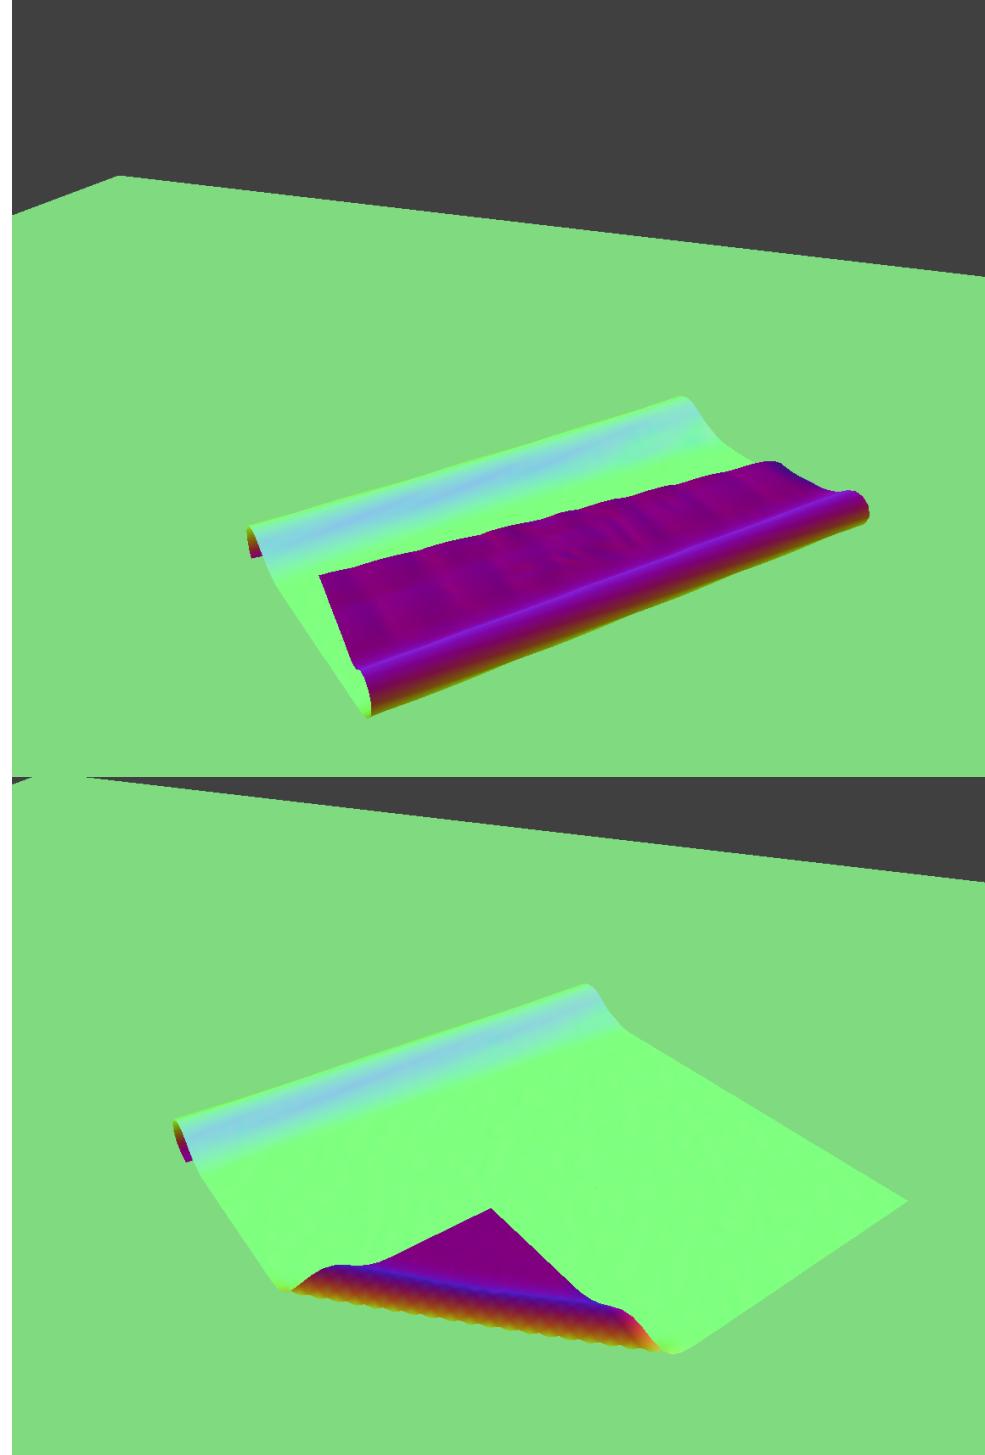

Low d ( $d = 1$ ,  $ks = 5000$ )

Lowering d means that there are less masses representing our cloth mesh. This is reflected by how the folds resulting from the self-collision are much thicker than a cloth with higher d. The cloth almost seems bouncier.

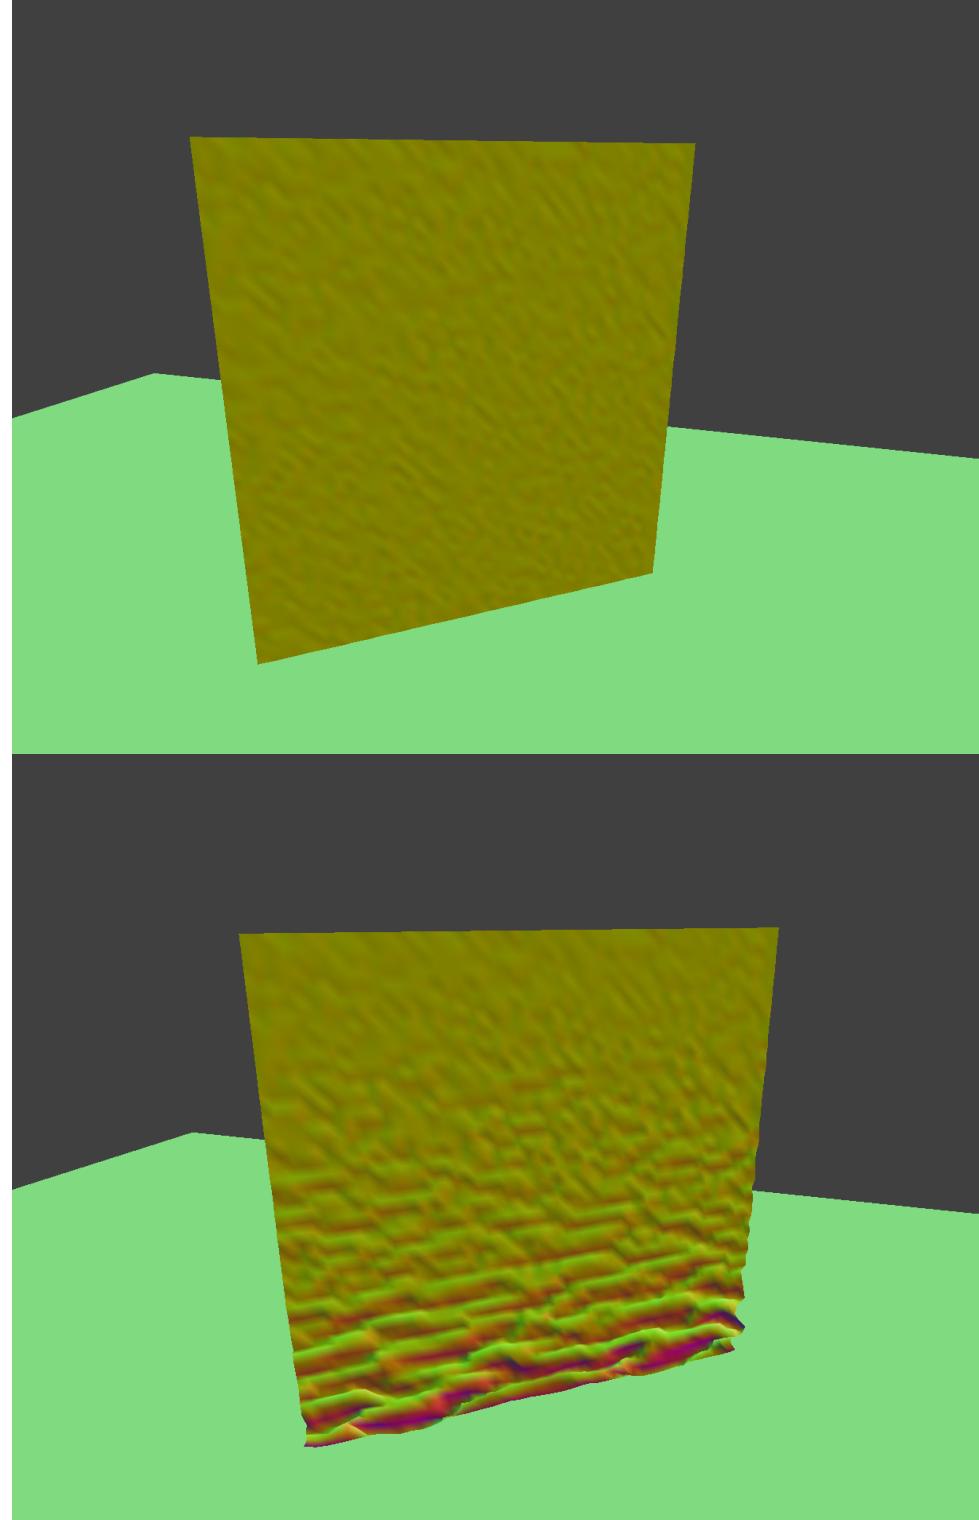

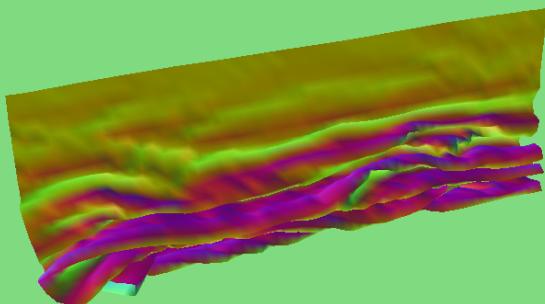

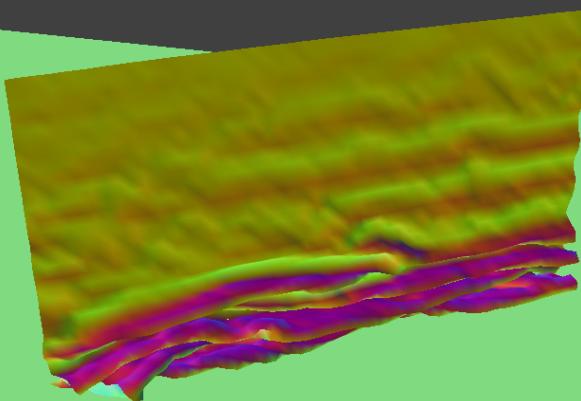

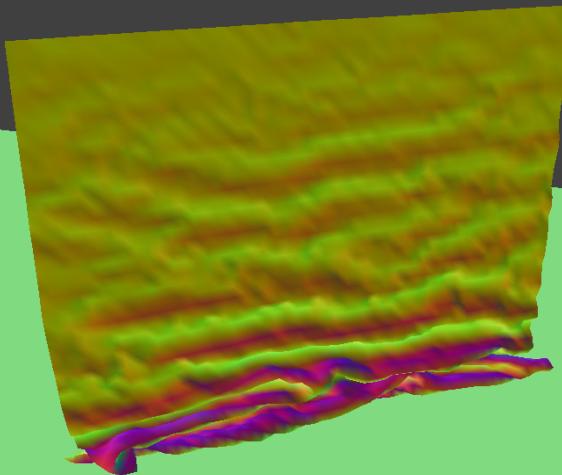

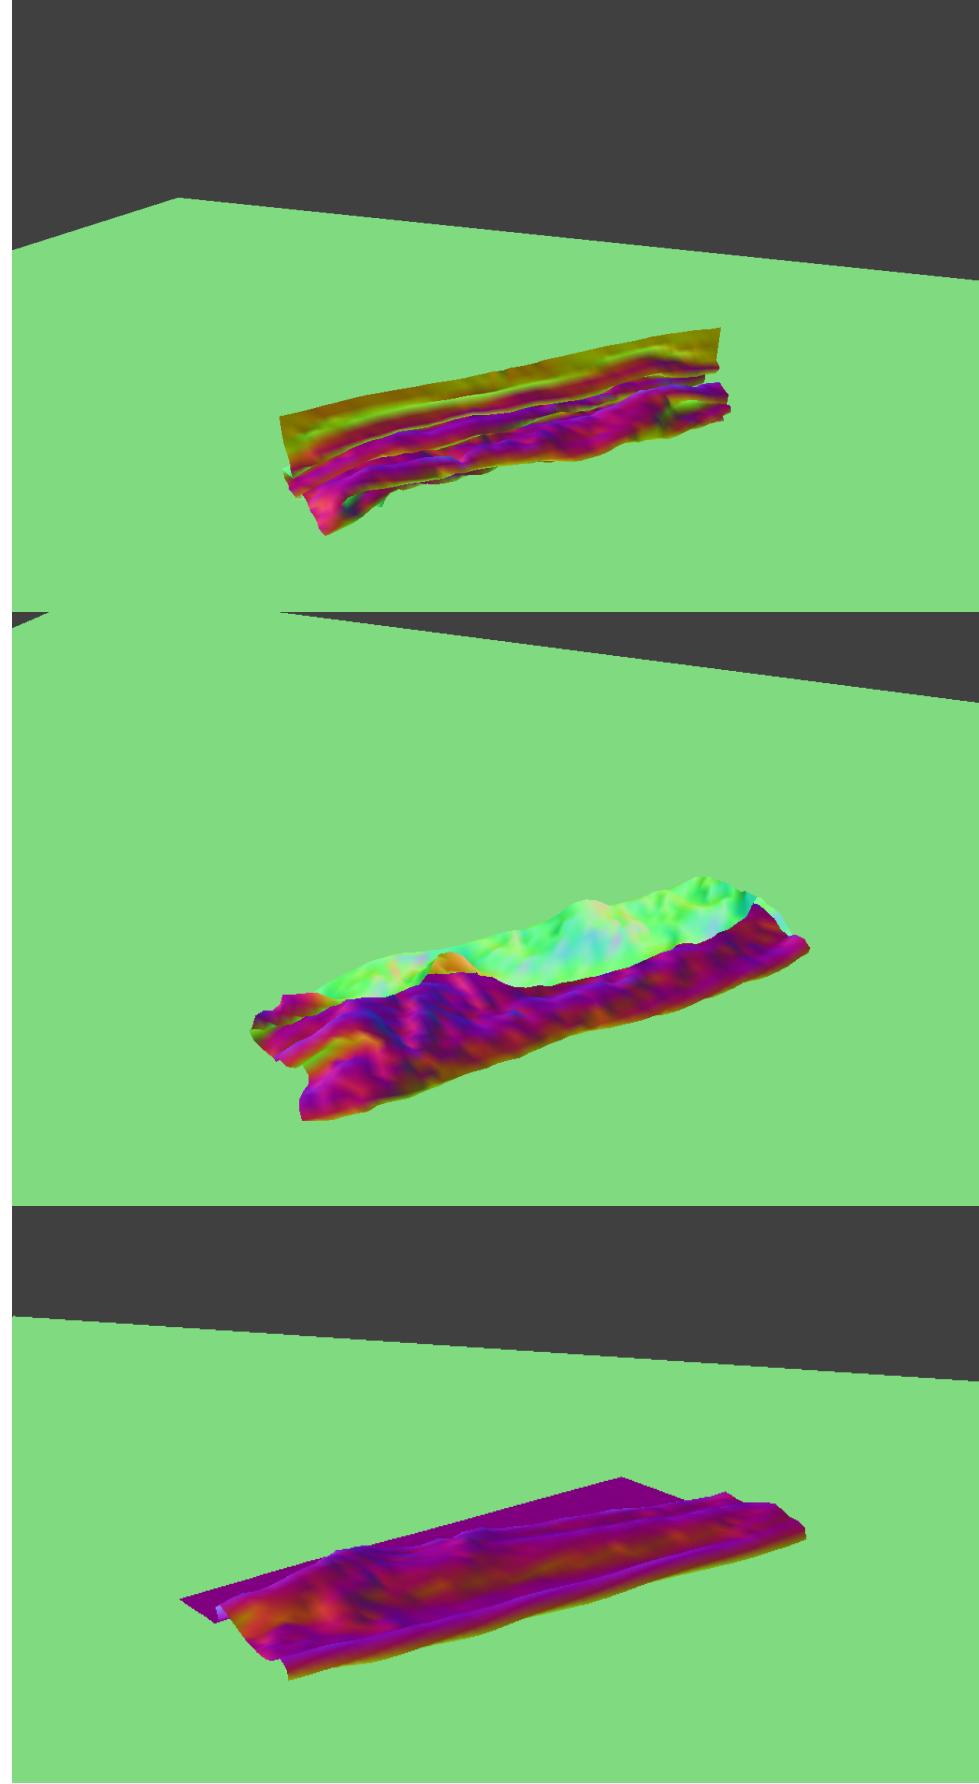

**high d (d = 30, ks = 5000)**

Raising  $d$  means that there are more masses in our cloth mesh. This is reflected by how the folds resulting from the self-collision are much finer than a cloth with lower  $d$ . The cloth ends up with very fine creases. The fabric seems like one that has very fine fibers, like silk.

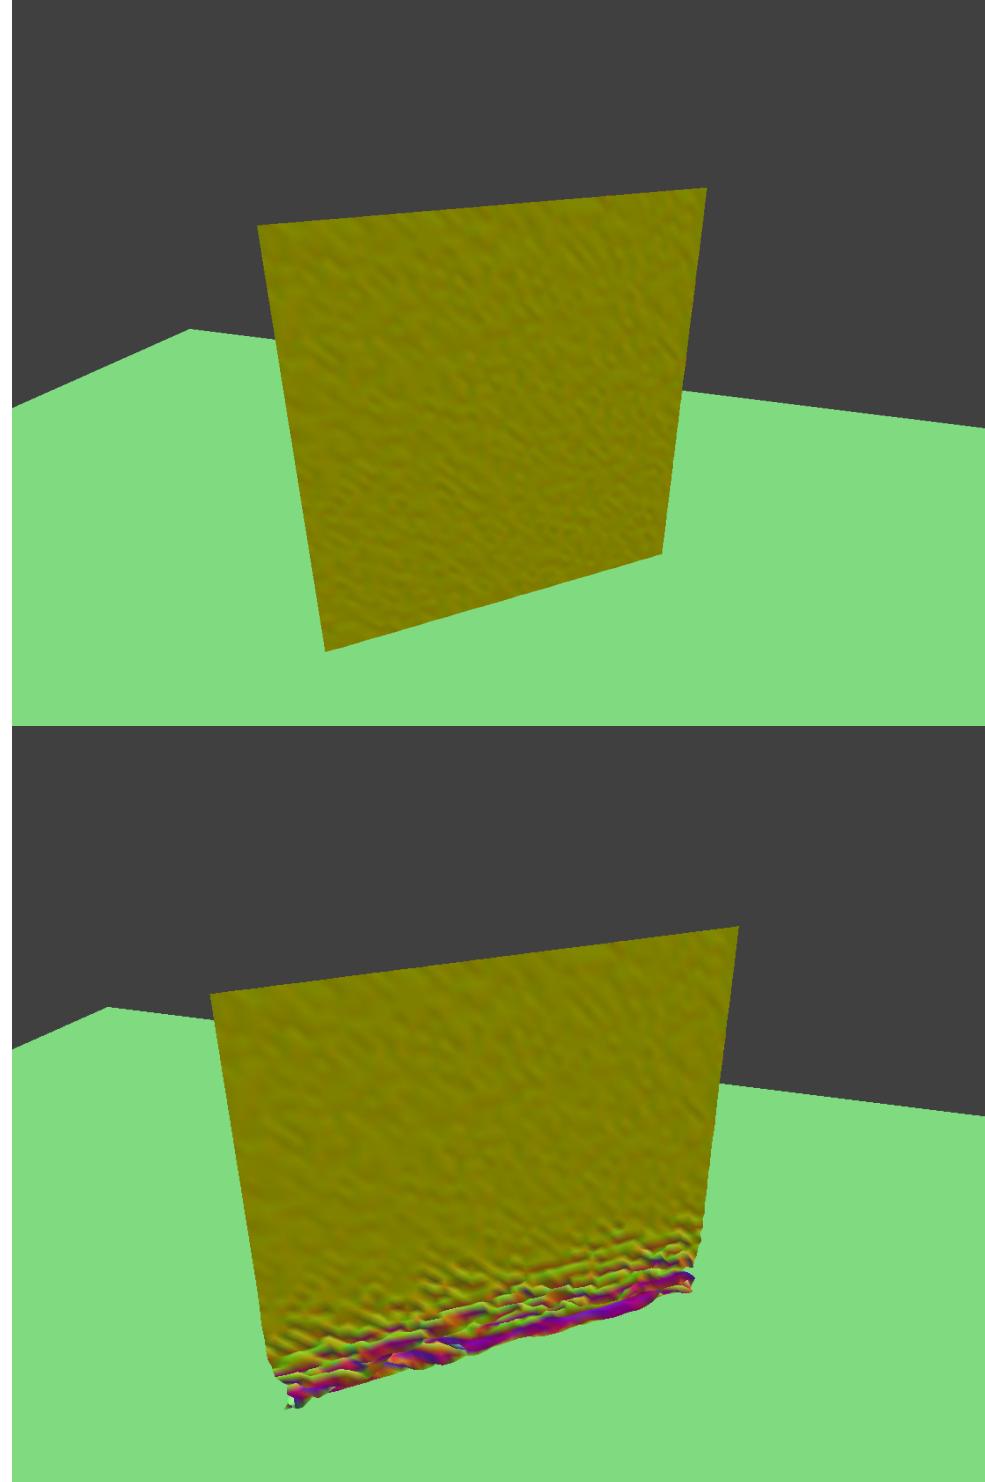

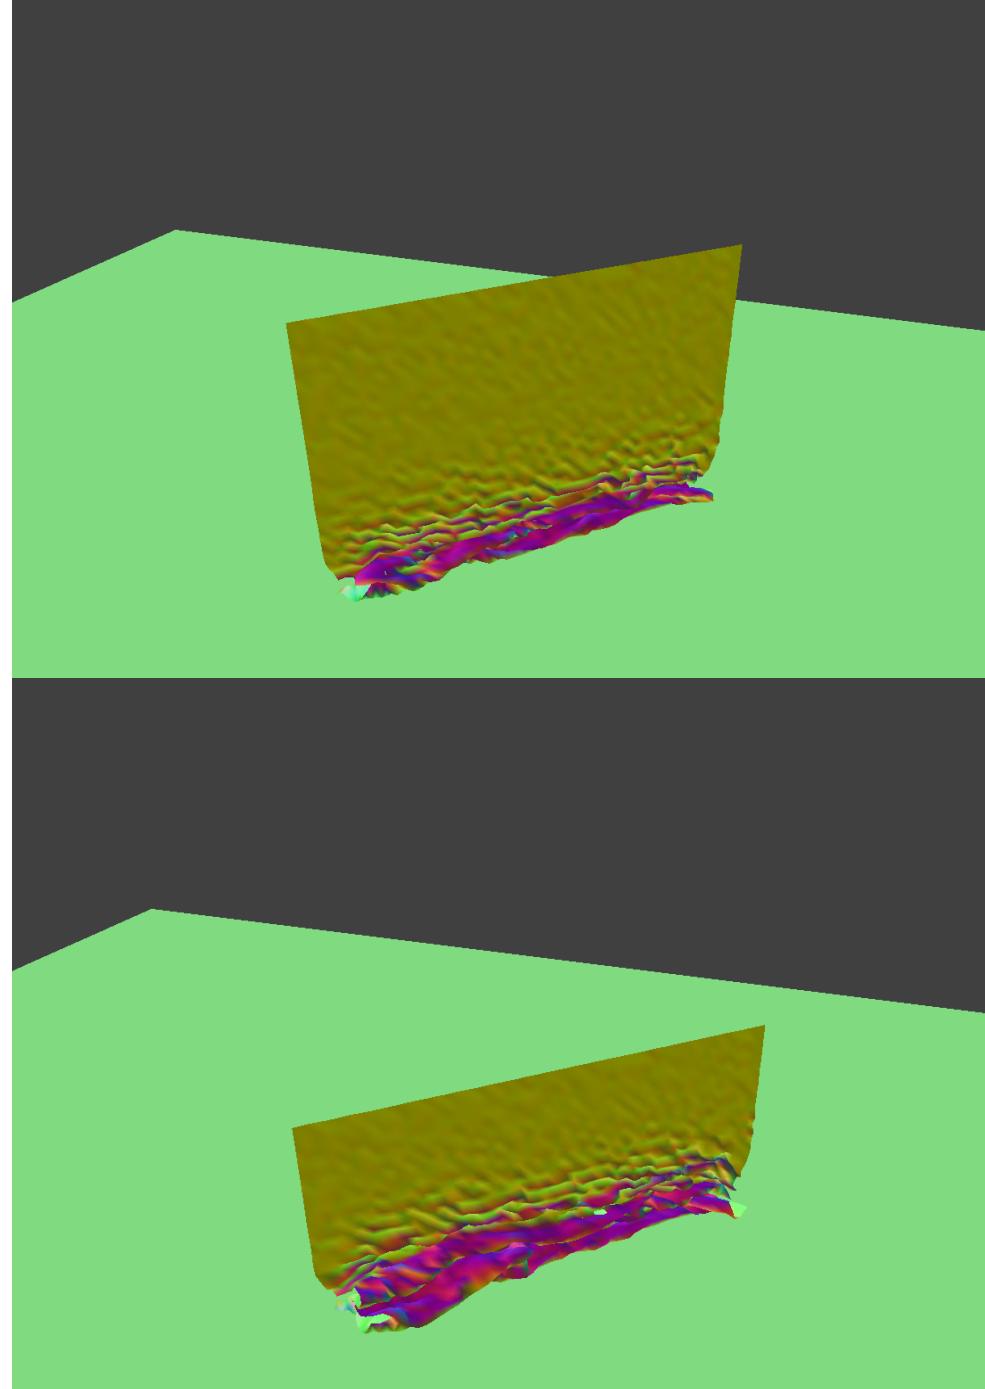

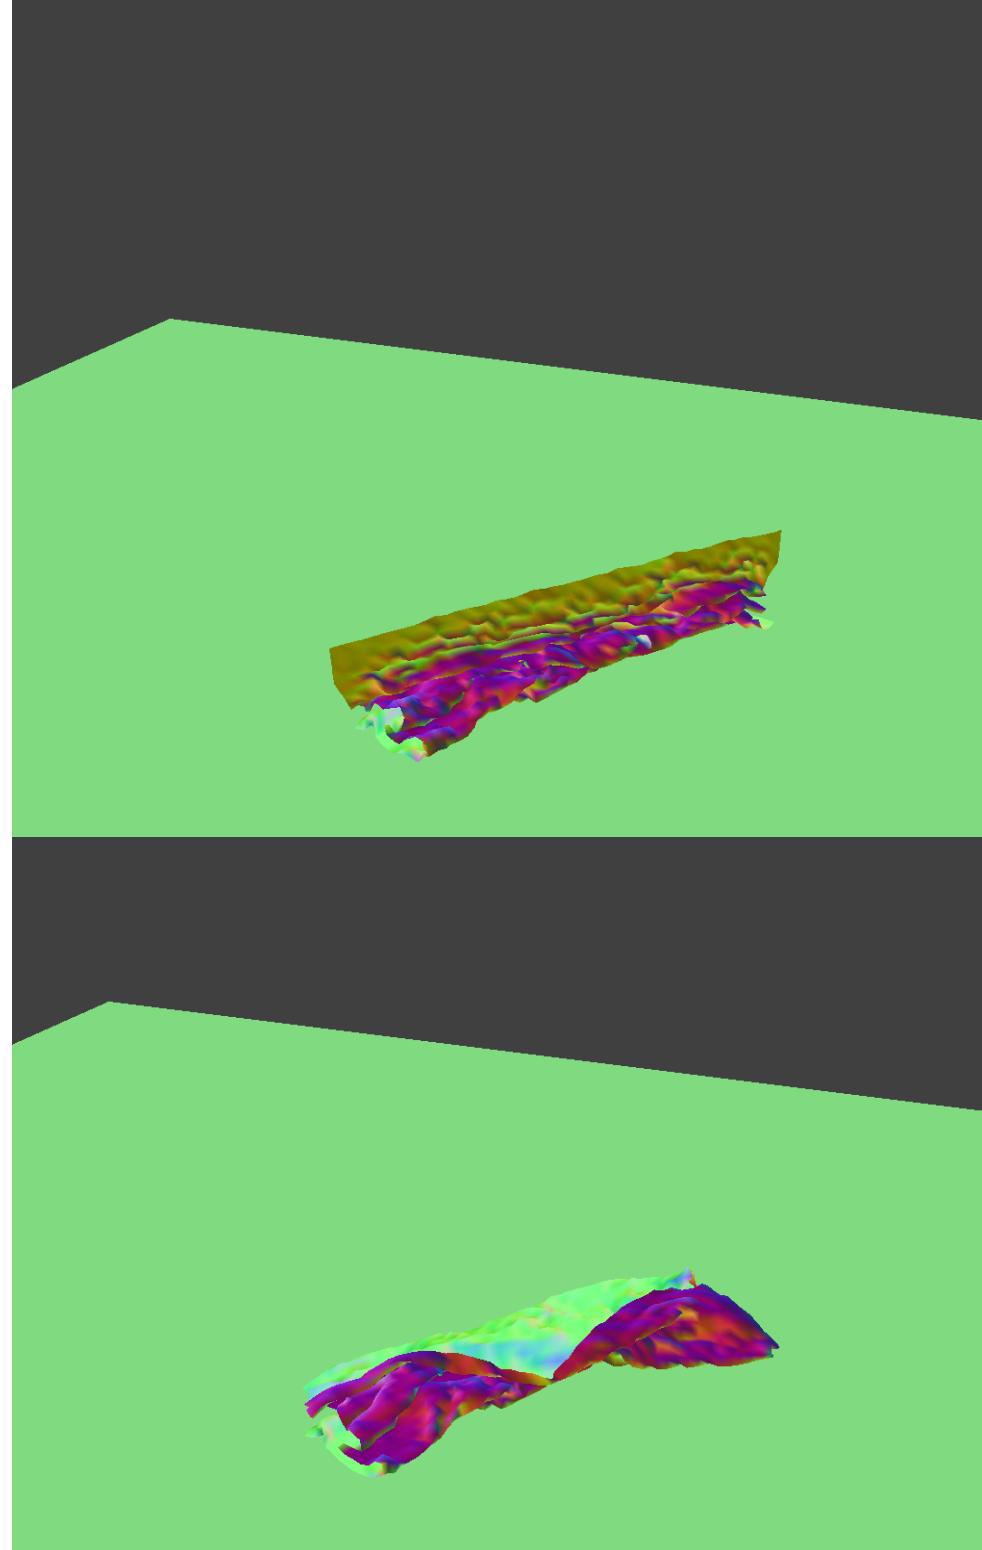

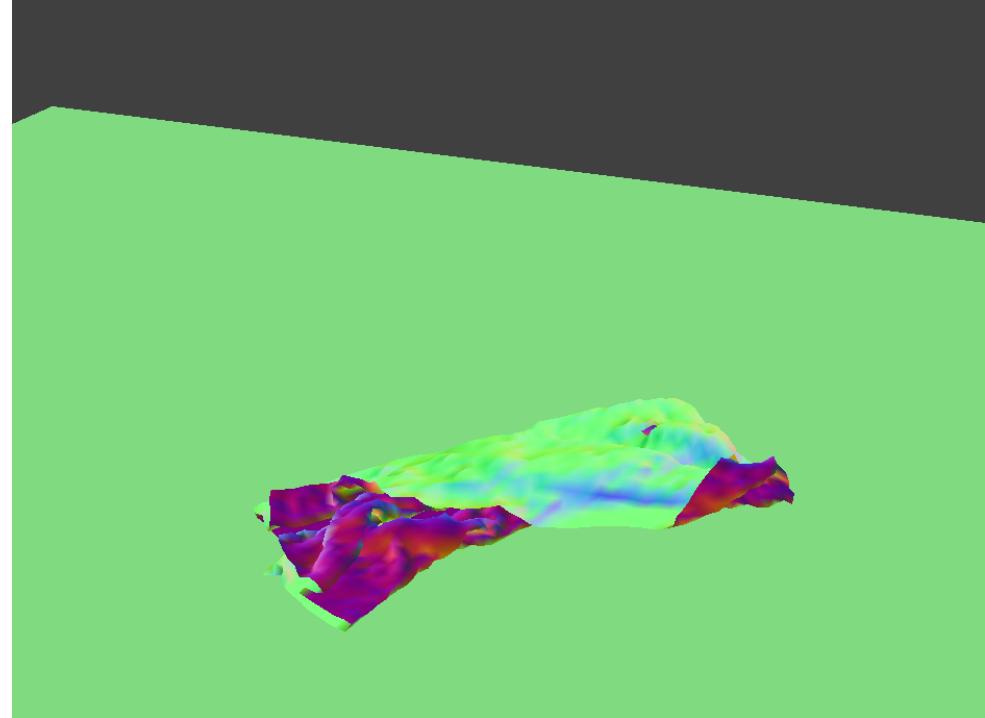

**low ks (d = 15, ks = 100)**

Lowering ks means we are lowering the spring constants of the springs connecting the masses in our cloth mesh. Lowering ks results in a cloth crumples very easily and doesn't maintain its shape well. As you can see, the cloth ends up in a resting state that has a lot of bumps, especially compared the other resting states.

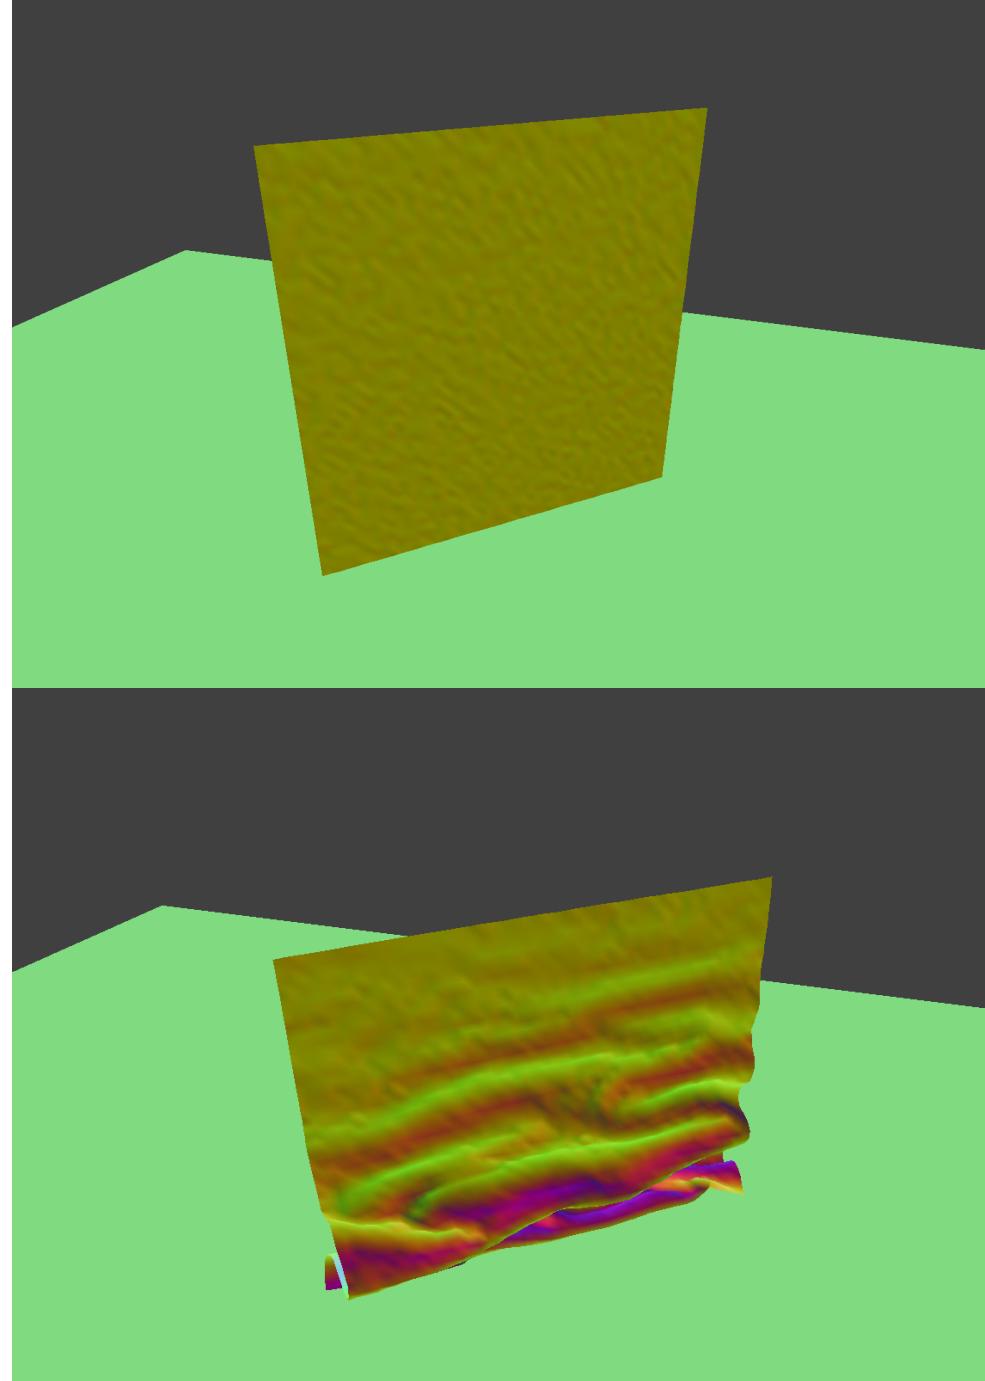

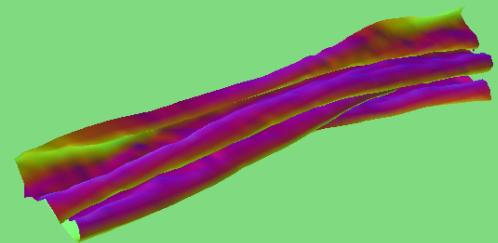

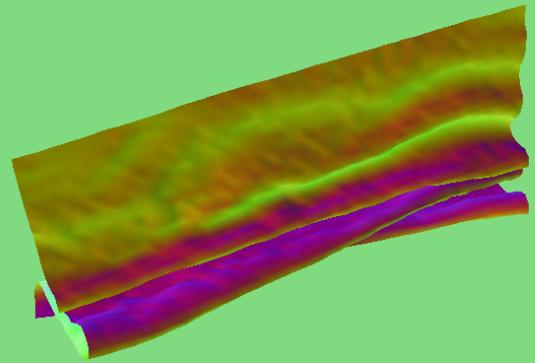

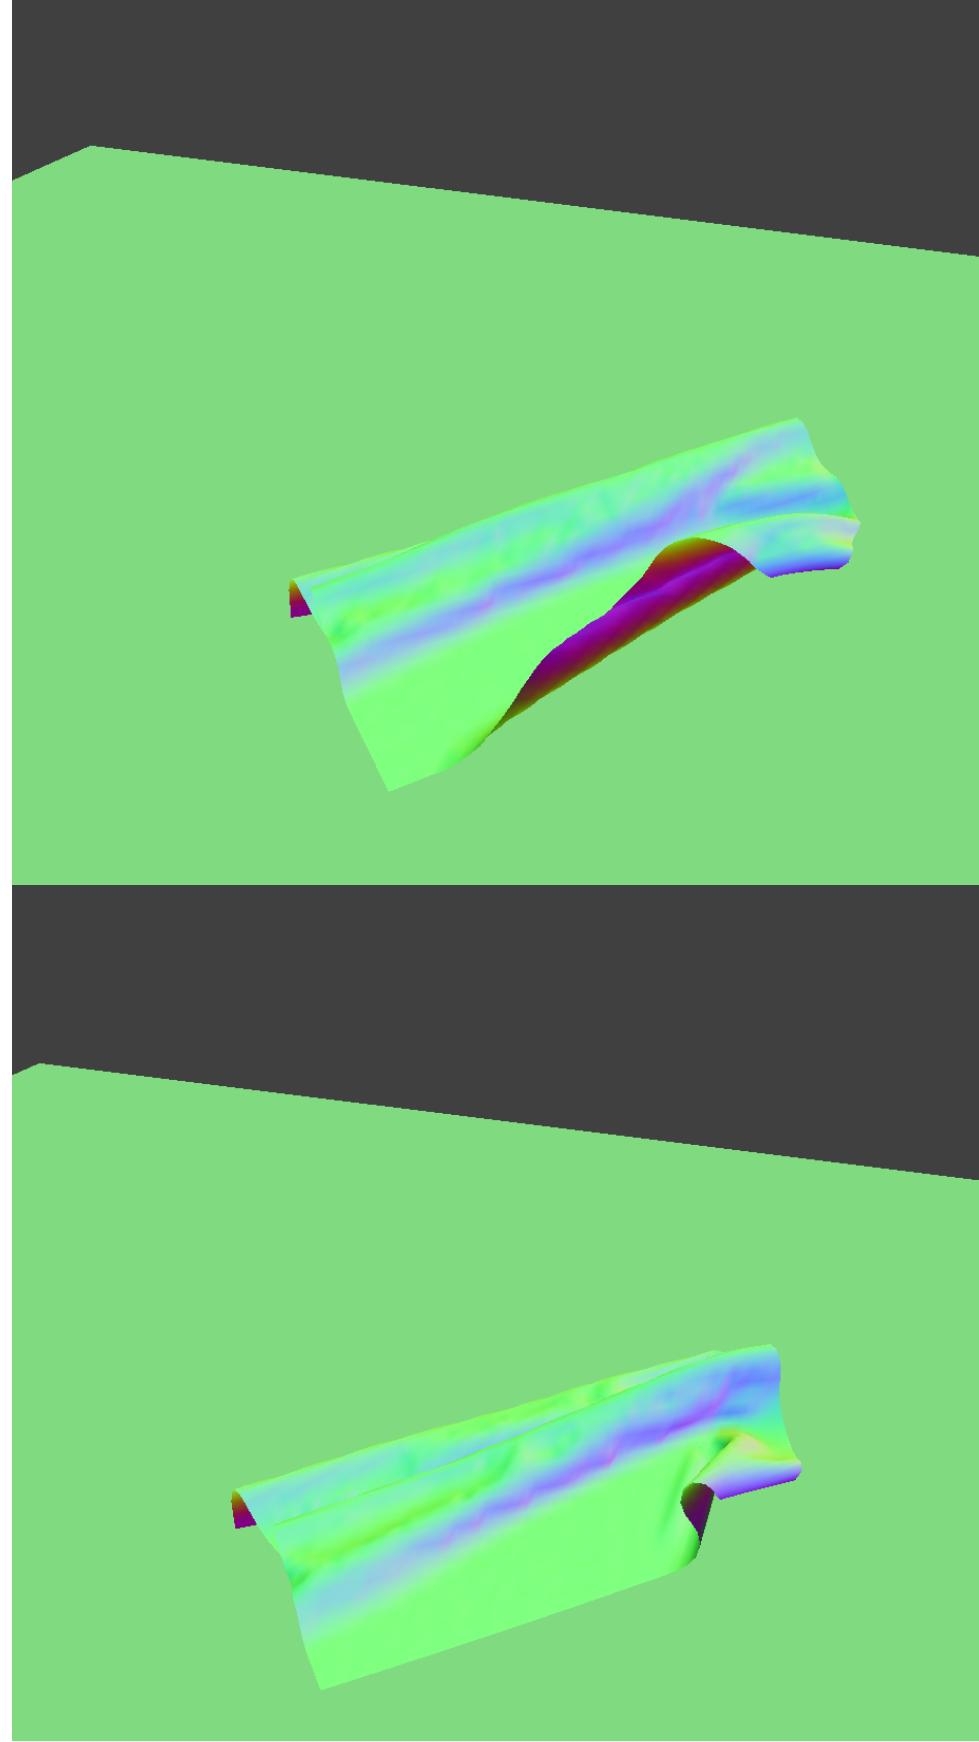

High ks ( $d = 15$ ,  $ks = 20000$ )

Raising ks means we are raising the spring constants of the springs connecting the masses in our cloth mesh. Raising ks results in a cloth that tends to want to maintain its shape after collision. As you can see, the cloth wrinkles are much thicker than when we had a low ks, and the cloth also comes to a much flatter resting state.

## Part 5

A shader program is an isolated program that runs in parallel on a GPU while most of the other rendering computations are done on CPU. Vertex shaders transform vertices by updating their position or normal vectors. Fragment shaders compute a color from the position and normal vectors computed by the vertex shaders. Both combined together can create the lighting effects we implemented in Project 3.

### Blinn-Phong Shading model

Blinn Phong shading accounts for ambient lighting, diffuse reflection, and specular highlights. Ambient lighting is shading that does not depend on anything. It is used to account for disregarded illumination and fill in black shadows. We treat this as a constant value. Diffuse reflection is independent of viewing direction and gives the intrinsic color of the surface. We model this by multiplying the diffuse coefficient with the source illumination and the dot product of the normal and the lighting direction. Specular highlights are computed using a dot product of the normal and the bisector of the vector from the intersection point to source and intersection point to camera.

We add these three terms to get our final Blinn-Phong shading model.

In bump mapping, we modify the normal vectors of an object so that we give the illusion of detail on the surface. We use a given height map to calculate the local space normals as we traverse across a texture, and use this calculation to modify the original surface normals.

On the other hand, in displacement mapping, not only do we modify the surface normals, we also modify the position of the vertices in the direction of our computed space normal vectors. We do this by moving the vertices in the direction of our computed space normal vectors.

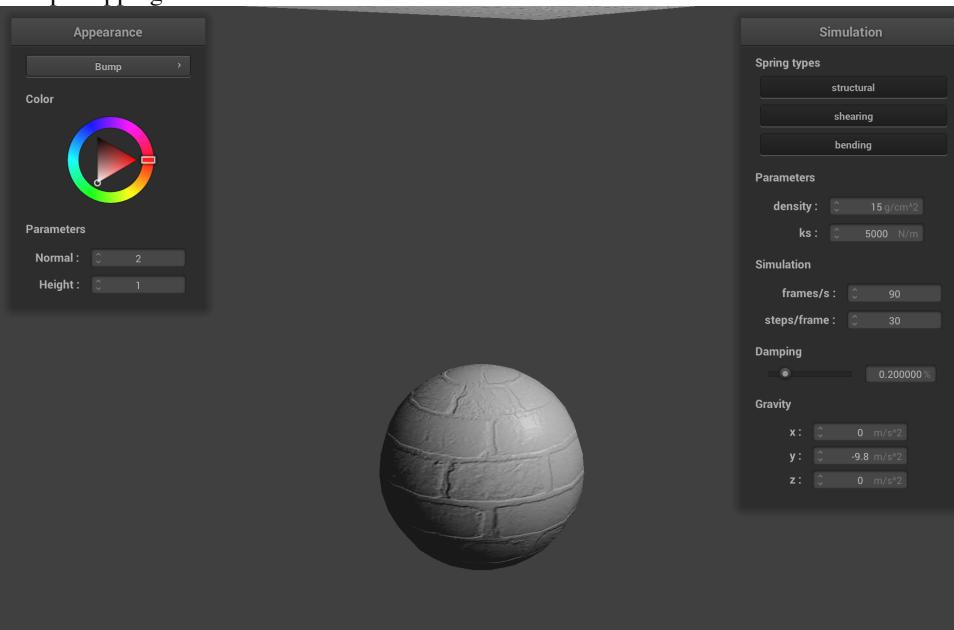

These two approaches result in different renders. While the bump mapping gives us the illusion of texture when looking straight on at a surface, the edges look very obviously smooth. For example, if the sphere were truly brick textured, we might expect see to have the ridges in the edge of the sphere, but it instead it looks smooth. On the other hand, the displacement mapping does have those bumps and ridges in the surface itself. This lends it a more realistic look in this specific rendering.

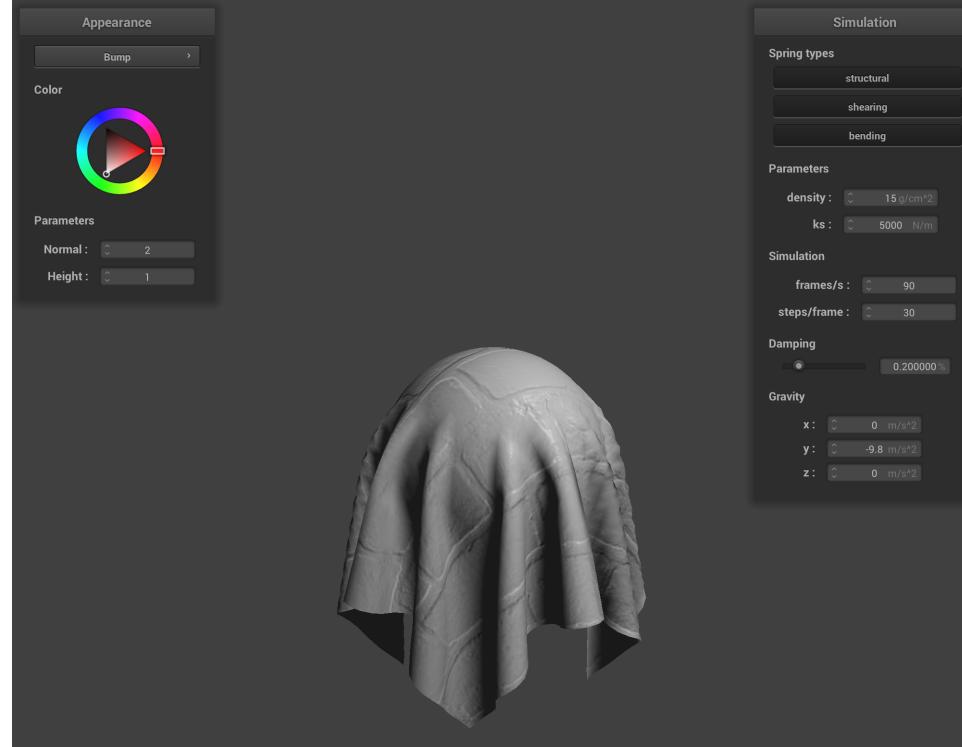

### Changing Mesh Coarseness

We varied the coarseness of the meshes and compared our two shader approaches. We noticed no difference for the bump mapping shader, but we did notice that the displacement mapping looking noticeably smoother and more realistic with the finer mesh. This is because for the bump mapping shader, we only modified the fragment shader, which is run on each pixel regardless of mesh coarseness. However, with displacement mapping we also modified the vertex shader. As we change the mesh coarseness, we also change the sphere vertices, which affects how finely grained our textures will appear.
